**PERFORMANCE OF FENCES ON THE PROTECTION OF ALFALFA
GROWN AT SIWA AEOLIAN SAND**

BY

Zaghloul, A.K.

Sand dune department, Desert Research Center Matariya, Cairo

ABSTRACT

The experiment was implemented in aeolian sand deposits at Siwa Oasis, Western Desert of Egypt, during 2004/2005 to study the performance of fences types for protection and productivity of alfalfa crop. Fences of single and double rows of palm leaves were investigated as well as their distance from the alfalfa fields i.e. (10, 20,30and 40m). Sand collectors were used for quantity and monitor the shifting sand in front and behind the fences. The combination of double rows fence and 10,20m distance gave superior growth characters and yield of alfalfa, while the best protection was occurred with the fence of double rows and 20m distance. This treatment decreased the wind speed and trapped most of sand drift which encroachment of alfalfa crop.

Keyword: Aeolian sand deposits, fence, windbreaks, checkerboard, Alfalfa, sand collectors, sand encroachment control, sand accumulation.

INTRODUCTION

The aeolian sand deposits are dominant phenomena in the arid regions. In Egypt, such areas cover 16% of the total surface area. The major portion of this area (95%) is located in western desert. Siwa Oasis is a natural depression of the western desert, it located at the northern edge of the Great Sand Sea. Agriculture land, irrigation system and drainage network are subjected to sand encroachment. It is true problem in Siwa Oasis. Few local trials such as fencing, windbreaks and cultivation of some plant species, have been used to control sand encroachment. Some trials to stabilize sand encroachment had been executed at 17 km to the west of Siwa. Draz and Missak (1992) indicated that establishment of successive mechanical fences in the transportation zone decrease the wind velocity and limit the sand supply from the source zone. Natural resources of plant materials such as palm leaves, reeds, dry plant residues are using temporary sand dune fixation. Zhang, *et al.* (2004) showed that, for corn straw fencing, wheat straw construction checkerboard system and planting *Artemisia halodendron*, have significant increases plant species diversity, vegetation cover, aboveground biomass and belowground biomass. Also, control of moving sand dunes caused enrichment the natural plants. Olsen (1985) reported that the average increase in yield up to distance of 20 times the height of the hedge amounts to the following result: barley 5.6%, rye 4.5% - fodder beets 14.6% turnips 6.4% - potatoes 9.2% and

clover grass 11.0%. Qiu, *et al.* (2004) showed that sand dune fixation with straw checkerboard technology proved both them icoenvironment condition and the stability of the dune surface.

The aim of this work was to study the model of fences and the best distance to obtain the best protection of the alfalfa crop.

MATERIALS AND METHODS

This work was designed to study the performance of fences to protect the alfalfa crop at Siwa research station (Khamisa farm) during the period 2004 to 2005.

Two factors for protection alfalfa crop were designed. The first factor consisted of two types of palm leaves fences as follows:- single row of fence – double rows of fences as one unit 10m apart and open area as control of date palm leaves, 72 m length, 2 m height and 35 % porosity. The fences were constructed vertical to dominant wind direction. The second factor was the distance from the fences to the alfalfa crop. The distances treatments were far 10, 20,30and40m from the fence.

Sand collectors were fixed before and after fence treatments to study the efficiency of fences for sand encroachment control (Bagnold, 1971). Alfalfa seed were broadcasted on October 20th 2004. The agricultural practices were applied by adding 10m³ sheep dung manure+150 kg super phosphate (15.5% P₂O₅)+50 kg ammonium sulphate (20.5% N). Four cuts were obtained of alfalfa crop. The first cut was after 60 days from sowing date, the second cut was after 60 days from the first one, third cut was obtained after 50 days from the second cut and the fourth cut was after 45 days from the third cut.

1- The growth characters and forage yield are studied as follows:-

- Plant height (cm) from cutting level to the junction the top most leaf.
 - Number of brunches per plant.
 - Fresh and dry weight per plant.
 - Number of alfalfa stems per one meter square at every cut, which was determined by using 0.5m² wooden frame. Estimation was made four times in each plot and their sum gives the number of stems/m².
 - Dry matter (DM) percentage for alfalfa in each cut, 200g random green sample was taken from each plot. Samples were oven dried and the DM% was then calculated.
 - Green forge yield (ton/fed) was determined for all cuts on the whole plot basis.
 - Dry forge yield (ton/fed) was calculated as follows: green forge yield (ton/fed) x dry matter percentage.
- 2- Amount of sands in sand collectors were monthly weighed during the period ranged from October 2004 to September 2005.
- 3- The amount of sand collected was used as indicator to determine the efficiency of trapping sand drift and protecting alfalfa field.

- The Fence efficiency (%): It was calculated using the following Formula = $\frac{A-B}{A} \times 100$ Where:

A

A= sand accumulation (gm/cm width) in front of fences.
 B= sand accumulation behind fences.

- 4- The chemical composition of both water used for irrigation and Aeolian sand deposits are presented in Table 1,2 by (FAO, 1970), respectively.
- 5- Average of climatic factors during the growth period is presented in Table (3).
- 6- The experiment design was a split plot design with four replications. The plot area was 10.5m². The main plots were assigned to fences types and the sub plot were occupied by the four distances between plant and fences
- 7- All data were subjected to the analysis of variance according to the method described by Snedecor and Cochran (1980). Regression coefficient was estimated according to (Harvey, 1987).

RESULTS AND DISCUSSION

I- Effect of fences and distances on the growth characters and yield:**I-I- Effect of fences:**

Data in Table (4) indicate that the fences significantly increased growth characters and yield i.e. plant height, No. of branches/plant, total fresh weight and dry weight/plant, No. of alfalfa stem/m², dry matter %, green and dry forage yield compared control (without fences). The increase of the forage yield during the four cuts was due to protection action of fences to the alfalfa plants. However, the double fences were superior than the single fence in the increase of the forage yield. Similar results were obtained by (Taichi *et al.*, 1994) who indicated that the effects of the use of double rows fences on the decrease of the wind velocity and on climatic improvement were cumulative in comparison with the effect of a single row of fence. This may be due to the effect of fences which minimize the sand drift and sand encroachment towards the plants. Moreover, the fences have improved the environmental condition, which gave the chance to the plant to growth well. (Frank and Willis, 1972) indicated that the existing of fences had the same effect.

Table (4): Effect of fences types on growth, yield component and forage yield of alfalfa in aeolian deposits at Siwa.

I- II- Effect of distance:

Increasing distance level from the fence significantly decrease plant height, No. of branches/plant, total fresh and dry weight/plant, No. of alfalfa stem, dry matter %, green and dry forage yield, (Table, 5). Regression coefficient (Fig 1 and 2) showed that negative effect between the distance and yield, this indicating that yield increase as the distance decrease and the contrary is true. The treatment

of 20 m gave the highest values compared with the other treatments in the most characters in the four cuts. On the other hand, no significant increase between 10, 20 m treatments, however, there are significant decrease between 20 m treatment and 30, 40 m treatments in all studied characters. These may be due to decrease of wind speed until 20 m. These results are in harmony with that obtained by (Olsen, 1985 and Mann, 1985).

I-III- Effect of the interaction between fences and distance:

The results in Table (6) indicate clearly that the interaction effect between fences and distance was significant on plant height and total fresh weight/plant in the 1st cut and No. of branches/plant, dry weight/plant, No. of alfalfa stem/m² in the 2nd cut. Also, plant height, total fresh and dry weight in the 3rd cut and total fresh and dry weight, dry matter, green and dry forage yield in the 4th cut. Generally, the combination of double fences and 10, 20 m distance gave the highest values for the respective characters. However, the control treatment and 40 m distance gave the lowest values in most characters. Forage and dry yield showed significant effect due to the distance and fences. However, the value of the forage and dry yield were superior up to 20m distance and double fence.

II- Effect of fences, distance and their interactions on sand accumulation:

II-1- Effect of fences:

Data in Table (7) and Fig (3) show that the regression coefficient of sand accumulation for fence treatments were significantly decreased compared the control (without fence). Double fences resulted the lowest values compared with the single fence however, the control treatment gave the highest value in sand deposits. The efficiency of fences on sand accumulation were 43.8 and 54.2% for single and double fences, respectively. These results due to the high efficiency of double fence in decrease of the wind velocity. Similar results were obtained by (Martin, 1985) who indicated that the efficiency of fences depended on the height and porosity.

II-II- Effect of distance:

Data in Table (8) and Fig (4) show that the regression coefficient was significantly different between 10, 20 m distance and 30, 40m treatments in all months. The differences were insignificant between the 10 and 20m.

However, there were no trends in the differences between 30 and 40m during the period of the experiment. The 10 m treatment gave the lowest values in sand deposits, whereas, 40 m treatment resulted the highest values in all months. The efficiency of distances were 43.8, 43.7, 28.1 and 22.7 % for 10, 20, 30 and 40m, respectively. These results may be due to the decrease of wind speed in the 10 and 20 m compared with the other treatments! The near distance of fences improved of the climatic conditions of arid lands and prevention desertification process. (Taichi *et al.*, 1994).

II-III- Effect of interaction:

Regarding the interaction efficiency, data in Table (9) showed that the treatments of double fence with 10 or 20m distance gave the highest records of

sand accumulation efficiency being to 66.6 and 63.0, respectively. Whereas, the distance of 40m without fence application gave the lowest value of sand accumulation efficiency. Generally, the combination of double fences and 10 m distance gave the lowest value. Whereas, the combination of the control and different distances obtained the highest values in most months.

Fig. (3): Regression coefficient between fences and sand accumulation.

Fig. (4): Regression coefficient between distance and sand accumulation.

Conclusion and recommendation:

With regard to these results, it could be concluded that fences and distance play an important role in the increase of growth characteristics and yield of alfalfa plants.

The best applied treatment was double fence + 20m distance. This treatment increased the total yield, which could be use in a wide scale. This due to the minimize the wind velocity that resulted in decreasing the transpiration and evaporation of the vegetative growth .This is leading to keep water and carbohydrate to the highest value, which increase the yield.

فعالية الأسوار في حماية البرسيم الحجازي المنزوع في الرواسب الرملية بسبوة

عبد الله قاسم زغلول

مركز بحوث الصحراء، المطرية، القاهرة

أقيمت تجربته لدراسة فعالية الأسوار في حماية البرسيم الحجازي المنزوع في الرواسب الرملية بواحة سبوة في الصحراء الغربية بجمهورية مصر العربية خلال الفترة من ٢٠٠٤-٢٠٠٥. وشملت التجربة عاملين. العامل الأول أسوار من جريد النخيل وتشمل (كنترول، سور، سور مضاعف) العامل الثاني: المسافة بين الأسوار والمحصول كانت ١٠-٢٠-٣٠-٤٠ م، كما وضعت مصائد الرمال أمام وخلف الأسوار وكانت أهم النتائج أن السور المضاعف + مسافة ١٠ و ٢٠م أعطت أعلى القيم في صفات النمو وكذلك محصول البرسيم الحجازي خلال الأربع حشاش بالإضافة إلى أن نفس المعاملة أعطت أقل القيم في كمية الرمال المتجمعة بعد الأسوار خلال فترة الدراسة. لذلك توصي الدراسة بزراعة البرسيم الحجازي علي بعد عشرة أضعاف من ارتفاع السور المقام لحماية هذا المحصول في مناطق الرواسب الرملية.
