The Protective Role of Folic Acid, Vitamin B12 and Vitamin C on the Mutagenicity of the Anticancer Drug Ifosfamide

Souria M. Donya, Fawzia A. Aly and Mona A. M. Abo-Zeid

Department of Genetics and Cytology, National Research Centre, Dokki, Cairo, Egypt

ABSTRACT

Ifosfamide (Holoxan, IFO) is an oxazaphosphorine alkylating agent with a broad spectrum of antineoplastic activity. IFO can damage DNA during any phase of the cell cycle and therefore, is not phase-specific. Thus the objective of this investigation is to measure the potential cytotoxicity of IFO alone and in combination with vitamins (FA, VB12 and VC) The genotoxic potential of IFO was evaluated *in vivo* using different mutagenic end points. Male Swiss mice were injected with different doses of IFO intraperitoneally to investigate the genotoxicity in somatic and germ cells. The doses were 8, 16 and 24 mg IFO/kg body wt. as single doses and 8 mg IFO/kg body wt. as a repeated dose for three consecutive days. Samples were collected after 24 h, 7 and 14 days after treatments. IFO induced chromosomal aberrations (in somatic and germ cells), SCEs and sperm shape abnormalities, which were highly significant in a dose dependent manner 24 h after treatments. Chromosomal aberrations were declined with increasing the time of recovery. However, the tetraploid cells in mouse bone marrow were increased. IFO increased the percentage of DNA fragmentation in mouse spleen cells as measured by diphenylamine (DPA) assay and confirmed by agarose gel-electrophoresis. Oral administration of folic acid (10 mg/kg body wt.), vitamin B12 (0.3 mg/kg) and vitamin C (50 mg/kg body wt.) declined the chromosomal aberrations in somatic and germ cells 24 h after concurrent treatment with IFO. The used doses of vitamins reduced the percentage of DNA fragmentation induced by 24 mg IFO/kg body wt. with DPA assay. In conclusion, the study indicates that the anticancer drug IFO is a mutagenic agent in mouse somatic and germ cells. Vitamins (FA, VB12 and VC) play a beneficial role against the mutagenicity of this drug.

Key Words: IFO, FA, VB12, VC, chromosomal aberrations, SCEs, sperm shape abnormalities, DNA damages.

INTRODUCTION

Ifosfamide is an oxazaphosphorine alkylating agent with a broad spectrum of antineoplastic activity. It is used alone or in combination regimens for the treatment of a variety of haematological malignancies such as lymphomas and multiple myeloma and solid tumors including sarcoma, ovarian, testicular, cervical, breast, lung cancer and bone tumors *(Dechant et al., 1991; Zhang et al., 2005 and Goto et al., 2007)* and is also used as systemic anticancer therapy in gynecological cancer patients with renal dysfunction *(Li et al., 2007)*. IFO destroys tumor cells through apoptosis initiated by DNA damage, modulation of cell cycle and other antiproliferative effects. IFO is used concurrently with the uroprotective mesna to avoid hemorrhagic cystitis *(Siu and Moore, 1998)*. According to many authors who studied the action of vitamins *in vivo*, the treatment protocols that yield the best result in terms of reduction of chromosomal damage were those in which vitamins (A, B12, C, E and FA) were administered as pre-treatment or in simultaneous treatment with the clastogenic agent *(Ghaskadbi et al., 1992; Aly et al., 2002 and Costa and Nepomuceno, 2006)*.

The present study was undertaken to assess the cytogenetic effect of IFO at different doses. The protective roles of FA, VB12, VC on the induced chromosomal aberrations was also studies.

MATERIALS AND METHODS

Test subastances:

Ifosfamide (Figure 1) was purchased from Holoxan, Baxter Frankfurt am Main, Germany. Based on *Paget and Barnes (1964)* evaluation of drug activities, it was used as reference to convert the human therapeutic dose to mice therapeutic dose.

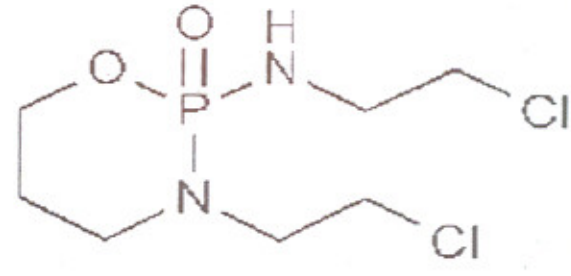

Figure 1: Ifosfamide

Folic acid (FA): Nile Co. for Pharm. and Chem. Ind. Cairo, Egypt.

Vitamin B12 (B12): Amriya Pharm. Ind., Alexandria, Egypt.

Vitamin C (VC): S.D.Fine-Chem.Ltd., Mumbai, India.

Cytogenetic studies:

Animals:

Laboratory-bred strain Swiss albino male mice of 8-10 weeks old with an average weight of 27.5+2.5g obtained from the National Research Center, Cairo, Egypt, were

used.Animals were housed in groups (5 animals/ group) and maintained under standard food and water ad libitium.

Doses and treatments:
IFO doses were i.p. administered at 8, 16, 24 mg/kg b.wt. as a single doses and repeated treatment for three consecutive days were conducted using the lowest dose 8 mg IFO /kg b. wt. Oral treatment of vitamins at 10 mg FA/kg b. wt., 0.3 mg VB12 /kg b.wt. and 50 VC /kg b. wt. were taken concurrently with 24 mg IFO/ kg. The anticancer drug IFO and vitamins were dissolved in distilled water.

Control groups of animals received distilled water and others received vitamins alone were collected concurrently with the treated groups.

Chromosomal aberrations in somatic and germ cells:
Samples were harvested after 24 h, 7 and 14 days of treatment with the different doses of IFO. The groups of animals received the concurrent administration of 24 mg IFO/kg b. wt. with each of the three vitamins separately were sacrificed after 24 h.

Sister chromatid exchanges (SCEs):
Samples were harvested 24 h after treatment with the different doses of IFO.

Sperm-shaped abnormalities:
Mice were treated once i.p. with each of the three doses of IFO. Samples were collected after 35 days from the treatments

Cytogenetic parameters:
For chromosomal aberrations in somatic and germ cells, bone-marrow metaphases were prepared according to *Yosida and Amano (1965)*. The diakinase-metaphase I cells collected from the spermatocytes were made following the air-drying technique of *Evans, et al. (1964)*. Slides were stained with 7 % Giemsa stain in phosphate buffer (pH 6.8). 100 well spread metaphases per animal were analyzed for chromosomal aberrations. The types of aberrations in bone-marrow cells included gaps breaks, deletions, fragments, centric fusions, centromeric attenuations. The types of aberrations in spermatocytes were XY univalents, autosomal univalents, fragments and breaks.

For sister-chromatid exchanges, the method described by *Allen (1982)* was adopted with some modifications. Bone-marrow cells were fixed and stained with fluorescence plus Giemsa method of *Perry and Wolff (1974)*. The frequency of SCE's was recorded for each animal in at least 30 metaphases.

For sperm- shape abnormalities, the epididymides were excised and minced in isotonic sodium citrate solution (2.2%). Smears were prepared and sperms were stained with Eosin Y. *(Wyrobek and Bruce, 1978)*. At least 1000 sperm per animal (5000/group) were assessed for morphological abnormalities of the sperm shape.

DNA Fragmentation Assay:
The groups of animals treated with different doses 8, 16 and 24 of IFO were collected 24h after treatments and repeated dose 8 mg IFO/kg b.wt. for three days. The other groups of animals received concurrently 24 mg IFO/kg b.wt. with each of the vitamins doses and were sacrificed 24 h after treatment.

The method of DNA fragmentation assay was carried out according to *Perandones, et al. (1993)*. Mouse spleen was mechanically dissociated in hypotonic lysis buffer. The cell lysate was centrifuged at 13.000xg for 15 min. then, the supernatant containing small DNA fragments was separated immediately and half the supernatant was used for gel-electrophoresis. The other half, as well as the pellet containing large pieces of DNA were used for the colorimetric determination by Diphenylamine (DPA) assay.

Statistical Analysis:
The significance of the results from the control data was calculated using ($2X^2$ contingency Table) for chromomosal aberrations in somatic and germ cells and t- test for SCE's, sperm- shape abnormalities and DNA fragmentation assays.

RESULTS

Cytogenetic effect of IFO:
Effect of IFO on somatic cells:
Chromosomal aberrations in bone marrow cells:
Table (1) illustrates a detailed study of single and repeated treatments with IFO for 24 h, 7 and 14 days on the induction of chromosomal aberrations in mouse bone marrow. The percentage of induced aberrations increased by increasing the dose of IFO. It was found to be statistically highly significant ($p<0.001$) after excluding gaps.The percentage of chromosomal aberrations decreased with increasing the time of recovery (Figure 2).

Sister chromatid exchanges (SCEs):
All the tested doses induced a statistically significant increase in the frequency of SCEs ($p<0.001$) over that of the control (Table 2) (Figure 3)

Effect of IFO on germ cells:
Chromosomal aberrations in diakinase metaphase I (spermatocytes):
Aberration rates of control animals showed no variation. The significant effect of IFO on the induction of chromosome aberrations in spermatocytes was observed after single and repeated treatment. The percentage of chromosomal aberrations was dose dependent and decreased as the time after treatment increased (Table 3) (Figure 4)

Sperm-shape abnormalities:
IFO induced a dose dependent and statistically significant increase in the percentage of sperm shape abnormalities. (Table 4) shows the different types of observed abnormalities (Figure 5).

The protective effect of vitamins:
Tables (5 and 6) demonstrated the protective effect of FA, VB12 and VC on the induction of the chromosomal aberrations in somatic and germ cells after concurrent treatment with IFO. The results showed that FA, VB12

and VC exerted a significant reduction in the percentage of chromosome aberration induced by 24 mg IFO/kg b. wt. as a single dose and 8 mg IFO/kg b. wt. for 3 consecutive days as a repeated dose.

DNA fragmentation assay:

Effect of IFO:

DPA assay:

Mean percentage of DNA fragmentation in mouse spleen cells was markedly increased ($p<0.001$) after treatment with the single and repeated doses of IFO (Table 7).

Agarose gel-electrophoresis:

DNA fragmentation assessed by agarose gel-electrophoresis was increased in a dose dependent manner with the increasing of IFO (Figure 6)

Protective effect of vitamins:

Table (8) illustrates the mean percentage of DNA fragmentation induced in mouse spleen cells after i.p. treatment with 24 mg IFO /kg b. wt. and oral concurrent treatment with 10, 0.3 and 50 mg/kg b. wt. FA, VB12 and VC, respectively. The percentage of DNA fragmentation decreased to 12.68%, 10.64% and 11.15% after treatment with FA, VB12 and VC, respectively, compared with 12.86% for IFO alone. (Figure 4) shows the DNA fragmentation assessed by agarose gel- electrophoresis, which was decreased after treatment with vitamins compared to that with 24 mgIFO / kg b.wt. (Figure 7)

DISCUSSION

Ifosfamide, as all other alkylating agents, destroy tumor cells through apoptosis initiated by DNA damage, modulation of cell cycle and other anti-proliferative effects. Thus it can damage DNA during any phase of cell cycle and therefore, it is not phase specific. The main mechanism is inhibition of DNA replication, as the interlinked strands cannot separate *(Zhang et al., 2005).*

IFO induced highly significant percentage of structural chromosomal aberrations in mouse bone marrow cells and diakinesis metaphase I cells (spermatocytes) which increased with dose increasing. Adler and El-Tarras *(1990)* demonstrated that cisplatine, an alkylating anticancer drug, induced chromosomal aberrations in primary spermatocytes and spermatogonial stem cells of male mice at 5, 7.5 and 10 mg/kg b.wt. Alvarez-Gonzalez, et al. *(2001)* found that IFO induced micronuclei in muose bone marrow cells. Also this was reported when injected i.p. tumor bearing mice at 90 mg/ kg for 1-3 days led to loss of IP+/-19q *(Leuraud et al., 2004).* Although the structural aberrations in mouse cells decreased with increasing the time of recovery, the numerical aberrations increased and reached their maximum after 14 days of recovery. The positive correlation between tetraploid cells and long duration of treatment may lead to induction of secondary carcinoma. This hypothesis supported with the study of *Kubota, et al. (1997)* who found that induction of secondary carcinoma appeared in patient treated with therapeutic regimens containing daunorubicin and cyclophosphamide. Also, they observed a third malignancy caused by alkylating agents (therapeutic regimens) containing IFO.

Separation of chromosomes forming XY and autosomal univalents was the most common type of aberrations in mouse spermatocytes in the present study. Concerning numerical aberrations, it is worth to mention that a very low frequency of triploid diakinasis metaphase I cells were observed after treatment with different doses of IFO. This phenomenon may be attributed to the effect of the anticancer on the spindle apparatus *(Temtamy et al., 1982 and Hemavathy and Krishnamurthy, 1988).* Such results agree with *Amer et al. (2002)* who observed triploid spermatocytes in mice treated with 1 mg Mitomycine C /kg b.wt.

IFO at single and repeated doses induced a highly significant and a dose dependent increase in SCE's frequencies in mouse bone marrow cells. The mean values of SCE's/cell were higher than three folds of the control indicating that IFO is a strong inducer of SCE. Induction of SCE's was observed in cultured V79 chinese hamster cells after treatment with IFO and cyclophosphamide *(Sirianni and Huang, 1980).* Aly, et al. *(2003)* demonstrated that both cisplatin and gemcitabine separately induced SCE's in mouse bone marrow cells in a dose dependent manner.

Sperm-head abnormalities are usually taken as a characteristic criterion and as an applied test for monitoring the mutagenic potential for many chemicals *(Brusick, 1980).* Tail deformities were reported to reduce fertility in human and animals *(Topham, 1983).*The mean percentage of sperm shape abnormalities were dose dependent with IFO. The maximum percentage was 7.92+0.21 ($p<0.001$) 24 h after treatment with 24 mg IFO/kg b. wt., such results coincide with the results obtained by cisplatin *(Giri et al., 1998),* Mitomycin C 1 mg/kg b.wt *(Farghaly and Ibrahim, 2003)* and cyclophosphamide at 20, 60 mg/kg b. wt. *(El-Nahas et al., 1989; Kumar et al., 2004 and Hassan et al., 2006)* which induced highly significant sperm shape abnormalities in mice.

Apoptosis is a form of programmed cell death shown to play a key role in normal development and oncogenesis. Its hall mark biochemical feature of endonuclease activation, give rise to internucleosomal DNA fragmentation *(Perandones et al., 1993).* The present study indicated the apoptotic changes induced by IFO in mouse spleen cells (*in vivo*) revealed a significant increase in the percentage of DNA fragmentation with (DPA) assay and was confirmed by agarose gel electrophoresis. The observed increase in DNA fragmentation might be due to the induction of DNA strand breaks by this compound. Many studies demonstrated that IFO have the potential to induce DNA fragmentation and apoptosis in various tissues *in vivo* and *in vitro*. Latz, et al. *(1997)* demonstrated that 1ug/ml IFO for 2 h induced DNA fragmentation in different cell lines *in vitro* such as V79 chines hamster,caski-(squamous ca.), widr-(colon ca.) and MRI-221 (melanoma) cells. Hartley, et al. *(1999)* observed the presence of DNA cross linking in the lymphocytes of patients treated with IFO at 3.09/m^2 /day by continous intravenous infusion over 3-5 days or as a 3h infusion daily for 3 days. Ypsilantis, et al. *(2004)* demonstrated that IFO induced enterocyte apoptosis and DNA fragmentation in the rabbit small and large intestine in a dose and intestinal site-dependent manner and it had a dose related apoptotic, but steady anti-mitotic effect on intestinal crypt cells, which led to mucosal atrophy in the small intestine of the rabbit.

The inhibition of DNA synthesis, specially the cellular DNA may be induced by cross links between the anticancer drugs and the DNA molecules. IFO generates bifunctional alkylating nitrogen mustards which are converted to chemically reactive carbonium ions at neutral pH and react with the 7-nitrogen atom of purine bases in DNA, especially when they are flanked by adjacent guanines. The second arm in phosphoramide mustard can react with a second guanine moiety in an opposite DNA strand or in the same strand to form cross links. The O^6 atom of guanine may also be a target for oxazaphosphorines *(Zhang et al., 2005)*

In a trial to minimize the genotoxicity effect of IFO. FA, VB12 and VC were administered simultaneously with single and repeat doses. The results showed that the maximum effect of FA appeared after repeated treatment in mouse bone marrow cells and spermatocytes. The possible mechanism of FA action is connected with thymidylate synthetase activity and through DNA synthesis *(Glover, 1982)* and with modifying cellular nucleotide pools *(Kunz, 1988).* Also, FA is involved in both methyl metabolism and in DNA synthesis and repair *(Duthie and Hawdon, 1998).* Donya and Aly *(2003)* found that FA caused a highly significant inhibition in the percentage of aberrant metaphases induced in mice somatic and germ cells after treatment with methotrexate (anticancer drug).

VB12 is required for the synthesis of methionine and S-adenosyl methionine, the common methyl donor required for the maintenance of DNA conformation *(Zingg and Jones, 1997)*. It is essential for one-carbon metabolism and cell division thus its synthesis is very complex and restricted to microorganisms *(Afman et al., 2001 and Ulleland et al., 2002)*. The percentage of inhibition reached 61.12% and 50.00% in mouse spermatocytes after single and repeated treatments with IFO plus VB12. The present results agreed with the studies carried out by *Joksic, et al. (2006)*, who demonstrated that VB12 reduced the incidence of micronuclei induced by ribavirin, a synthetic purine nucleoside analogue with a broad spectrum of antiviral activity, in phytohemaglutinine-stimulated human lymphocytes.

Oral administration of VC to mice treated with IFO (concurrent administration) minimized the percentage of chromosomal aberration induced in somatic and germ cells after both single and repeated treatments. VC is a powerful reducing agent (antioxidant) and plays a part in intracellular oxidation/reduction system and binding oxidants (free radicals) produced endogenously. Besides, VC can promote the removal of oxidative DNA damage from the DNA and/or nucleotide pool, through the upregulation of repair enzymes, perhaps induced by the vitamin's proxidative properties *(Cooke et al., 1998)*. Ghaskadbi, et al. *(1992) and Vijayalaxmi and Venu (1999)* reported that the modifying effect of ascorbic acid at low doses on cyclophosphamide induced micronuclei in mice. Also, Giri, et al. *(1998)* found that the frequency of all mutagenic parameters in Swiss albino mice treated with VC plus cisplatin were significantly less than those treated with cisplatin alone suggesting a protective role of ascorbic acid against cisplatin.

The concurrent administration of IFO at 8 mg/kg b. wt. with vitamins FA, VB12, VC reduced the percentage of DNA fragmentation in mouse spleen cells as measured by DPA and agarose gel electrophorasis. Simultaneous treatment of human peripheral blood mononuclear cells (in vitro) with cisplatin and melatonin (free radical scavenger and general antioxidant pineal hormone) decreased cisplatin induction of DNA fragmentation from 45% to 28% *(Hassan et al., 1999)*. VC diminished the extent of DNA damage evoked by selenium-cisplatin conjugate but had no effect on the kinetics of DNA repair in human lymphocytes *(Blasiak and Kowalik, 2001)*. But post treatment of VC for mice treated with cyclophosphamide did not affect DNA damage level using comet assay in peripheral white blood cells *(Franke et al., 2005)*.

The present study indicates that the anticancer drug IFO is a mutagenic agent in mouse somatic and germ cells. Vitamins (FA, VB12 and VC) play a beneficial role against the mutagenicity of this drug.
