## Mahdy et al 2012

## Introduction:

Cotton production in Egypt faces a serious constraint, notably delaying sowing date by the farmers to gain complete early winter crop before cotton. Therefore, cotton breeders in Egypt have to develop new cultivars adapted to late planting after early winter crops and early wheat cultivars. Narayanan et al. (1987) curtailed the days to first boll opening up to 25 days by disruptive mating and selection for earliness. Abdalla (1990) found that first sympodial node and earliness index were the best criteria for selecting early high yielding lines. Abo El-Zahab and Amein (1996a and b) reported that Egyptian cotton genotypes do differ in their response to the stress of late planting. Mahdy et $a l$. (2001a and b) found that two cycles of pedigree selection for earliness depleted the genetic variability of earliness and pedigree selection improved seed cotton yield and earliness in late planting. Mahdy et al. (2006, 2007, 2009 a and b) obtained superior families out yielded the better parent in seed cotton yield/plant, number of bolls/plant, seed index, lint index and earliness index by pedigree selection in Egyptian cotton populations in late planting. The present work aimed to isolate superior promising early and high yielding families in late planting.

## Materials and Methods:

Two cycles of pedigree selection for earliness index and lint
yield/plant were achieved in two segregating populations of Egyptian cotton (G. barbadense L.) under late planting condition at Assiut Univ. Exper. Farm during 2009 to 2011 summer seasons. The basic materials were two F6populations. Population I (pop. I) were 40 families stemmed from the cross [(Giza $8 \times$ Pima 56) x Giza 91)], and 38 families from population II (pop. II) stemmed from the cross (Giza 80 $x$ Dandara). In season 2009, the families of pop. I and pop. II along with the two parents and the unselected bulk sample were sown on May, $5^{\text {th }}$ in two experiments. A randomized complete block design of three replications was used in the three seasons. In the three seasons; the plot size was one row, 4 m long, 60 cm apart and 40 cm between hills within a row, after full emergence, seedlings were thinned to one plant per hill. In the three seasons the recommended cultural practices for cotton production were adopted through out the growing season, except for nitrogen fertilization. Only half of the recommended dose of nitrogen for cotton production was added after thinning and before the first irrigation. At the end of the growing season, two picks were done. The recorded traits in the three seasons were; seed cotton yield/plant; g.(SCY/P,g.), lint yield/plant; g.(LY/P,g.), lint percentage(LP), number of bolls/plant(NB/P), boll weight, g.(BW,g.); (average weight of 25 sound open bolls from each fam-
ily before the first pick), seed index; g.(SI,g), lint index; $\mathrm{g} .(\mathrm{LI}, \mathrm{g})$, earliness index(EI); (weight of the first pick/weight of the two picks), and days to first flower(DFF). The best plant from each of the best 20 families in lint yield/plant, and in earliness index was saved from each population. In season 2010, F7genreation; sowing date was on May, $1^{\text {st }}$. At the end of the season, the best plant from each of the best 10 families in lint yield/plant, and in earliness index from each population was selected for evaluation in season 2011. In season 2011, F8generation; the 10 selected families for lint yield/plant, and the 10 families for earliness index from the two populations were evaluated in separate experiments, one for each population. Data were subjected to proper statistical analysis according to Steel and Torrie (1980). Genotypes means were compared using Revised Least Significant Differences test (RLSD) according to El-Rawi and Khalafalla (1980). The phenotypic ( $\sigma^{2} \mathrm{p}$ ), genotypic ( $\sigma^{2} \mathrm{~g}$ ) variances, the phenotypic ( $\mathrm{pcv} \%$ ) and genotypic (gcv \%) coefficients of variability and heritability in broad sense ( H ) were calculated according to Walker (1960). Realized heritability ( $\mathrm{h}^{2}$ ) was calculated as; $\mathrm{h}^{2}=\mathrm{R} / \mathrm{S}$ (Falconer, 1989); where $R=$ response to selection and $S=$ selection differential. Narrow sense heritability was calculated as parent-
offspring regression according to
Smith and Kinman (1965).
Results and Discussions:
1- Description of the base populations in the F6-generation:
1.1- Means and variances:

The analysis of variance of the studied traits in the two populations, pcv, gcv and heritability in broad sense are shown in Table 1. Mean squares of the families of the two populations were significant for all traits indicating the presence of variability in the criteria of selection.
The family means (Table 2) showed wide range in all traits. In pop.I,seed cotton yield/plant ranged from 25.48 to 63.66 with an average of 39.35 g ., lint yield/plant ranged from 9.74 to 25.15 with an average of 14.98 g., number of bolls/plant ranged from 9.93 to 23.25 with an average of 15.74 , and earliness index ranged from 0.51 to 0.97 with an average of 0.82 . Similar ranges were observed in pop. II. Such wide ranges reflected in high estimates of pcv and gev. High estimates of gcv were observed in seed cotton yield/plant (23.61 and $26.59 \%$ ), lint yield/plant ( 23.70 and $27.60 \%$ ) and number of bolls/plant ( 21.61 and $29.78 \%$ ) in pop. I and II; respectively. Boll weight, earliness index and seed and lint indices showed moderate variability. However,lint percentage and days to flowering showed narrow estimates of genetic variability. The close estimates of gcv and pcv resulted in very high unreliable estimates of broad sense heritability, which reached in lint yield
to 93.78 and $94.88 \%$, and in earliness index to 98.35 and $98.11 \%$ for pop. I and II; respectively. This could be due to two main causes; firstly, evaluation of the families at one site for one season inflated the family's mean squares by the confounding effects of the interactions among families, years and locations. Secondly, the preponderance of dominance and over-dominance in early segregating generations.
2- Pedigree selection for earliness index:
2.1- Variability and heritability estimates:
Mean squares of the selected families for earliness index and the other traits was significant ( $\mathrm{P}<0.01$ ) after two cycles of selection in the two populations (not included). The pcv and gev of earliness index in pop. I decreased from 13.46 and $13.35 \%$ in the base population(Table1) to 8.28 and $8.12 \%$ after two cycles of selection (Table 3). Similar decrease in variability was also observed in pop. II. The close estimates of pcv and gev resulted in very high and unreliable estimates of broad sense heritability in the two populations for all traits except for boll weight and days to first flower in pop. I. Otherwise, the realized heritability of earliness index was 0.4550 in pop. I and 0.2731 in pop. II (Tables 3 and 5). Parentoffspring regression was very low for the criterion of selection; earliness index and was 0.1127 in pop. I and 0.1311 in pop. II (Table 5). The wide differences between broad sense heritability as
estimated from the expected mean squares, realized heritability and parent-offspring regression could be due to the two main causes mentioned before, in addition to that the realized heritability and parent-offspring regression depend only upon the additive variance transmitted from generation to generation. The only criticism of realized heritability estimates in this research was the calculation of the selection differential in a season and genetic gain in another season, in which the genotype by environment interaction could affect these estimates. Heritability estimates from parent-offspring regression could be also affected by genotype-environment interaction, in which the parents and offspring were grown in two different seasons. Generally, it could be concluded that the realized heritability and parentoffspring regression estimates were more reliable than the broad sense heritability in the two populations. Singh et al. (1995) found significant genotypic differences for all traits in the F3 and F4-generations. Lloyd and Bridges (1995) practiced selection at conventional and late plantings and found significant genotypic variation for all traits. Mahdy et al. (2006) found that the gev after two cycles of selection for earliness index ranged from16.06 to $19.16 \%$. Mahdy et al. (2009b) noted that the gev after two cycles of selection for earliness index was 13.65 and $17.30 \%$ in two populations, and
the realized heritability was 0.4598 and 0.4099. Hassaballa et al.(2012)came to the same conclusion and found realized heritability of 0.4214 and 0.3649 in two populations at late planting.

## 2.2- Means and observed gain in population I:

Mean earliness index (Table 3) ranged from 0.77 to 0.96 with an average of 0.89 . Most of the ten selected families for earliness index which showed high earliness index (Family No. 8, No. 11, No. 97, No. 136 and No. 144) were low in yielding ability. However, two promising families; No. 2 and No. 175 showed significant ( $\mathrm{P}<0.01$ ) observed gains (Table 4) from both of the bulk sample and the better parent in earliness index and yield. The direct observed gain in earliness index accounted for 12.78 and $9.72 \%$ from the bulk sample, and for 16.95 and $13.78 \%$ from the better parent for families No. 2 and No. 175; respectively. Family No. 175 showed significant ( $\mathrm{P}<0.01$ ) correlated gains of 26.81, 49.99, 18.17, 9.87 and $43.19 \%$ from the better parent for seed cotton yield/plant, lint yield/plant, lint percentage, seed index and lint index; respectively.

## 2.3- Means and observed gain in population II:

Mean earliness index of the selected families ranged from 0.62 to 0.94 with an average of 0.82 compared to 0.79 for the bulk sample and 0.83 for the better parent Dandara (Table 5). The
response to selection in pop. II was better than in pop. I. The average of the ten selected families (Table 4) showed significant ( $\mathrm{P}<0.01$ ) direct gain in earliness index of $3.80 \%$ from the bulk sample and insignificant $1.20 \%$ ) from the better parent accompanied with significant ( $\mathrm{P}<0.05-<0.01$ ) correlated gain of $7.89 \%$ for seed cotton yield/plant, $12.90 \%$ for lint yield/plant, $5.34 \%$ for lint percentage, $8.82 \%$ for boll weight, $2.36 \%$ for seed index and $14.59 \%$ from the better parent. Furthermore, two superior promising families; No. 11 and No. 151 were obtained. The two superior families characterized by significant ( $\mathrm{P}<0.01$ ) gain from the bulk sample and the better parent for earliness index, seed cotton yield/plant, lint yield/plant and most of the other traits. These results are in general agreement with those obtained by Narayanan et al. (1987), Abdalla (1990), Mahdy et al. (2001b), Mahdy et al. (2006) and Hassaballa et al. (2012).
3. Pedigree selection for lint yield/plant:
3.1- Variability and heritability estimates:
The families mean squares of the selection criterion, lint yield/plant and the other traits were significant ( $\mathrm{P}<0.01$ ) in both populations (not included). The pcv and $\mathrm{gcv} \%$ (Tables 6 and 8 ) were high for lint yield/plant, seed cotton yield/plant and number of bolls/plant, and moderate for the other traits except days to

## Mahdy et al 2012

first flower, which were low in the two populations. The gcv of lint yield/plant was 22.59 in pop. I and $21.50 \%$ in pop. II indicating sufficient genetic variability for further cycles of selection. The close estimates of pcy and gev \% resulted in very high and unreliable estimates of broad sense heritability. However, the realized heritability for the criterion of selection was low in pop. I (0.4128) and in pop. II (0.3970). Furthermore, parentoffspring regression was very low after two cycles of selection and accounted for 0.1528 in pop. I and 0.1459 in pop. II. The wide differences between broad sense, realized heritability estimates and parent-offspring regression were interpreted before, and reflect the effects of dominance and overdominance in the F8-genreation in these materials. Lloyd and Bridges (1995) found significant genotypic variation for all traits at conventional and late plantings of cotton. Okasha (1998) noted high to moderate broad sense heritability estimates for all traits in a study of direct selection for yield and yield components. Mahdy et al. (2001a and b) and Mahdy et al. (2012) are in line with these results.

## 3.2- Means and observed gain in pop. I:

Mean lint yield/plant (Table 6) ranged from 7.78 for family No. 82 to 20.77 for family No. 184 with an average of 15.48 g . Six families (No. 95, No. 128, No. 140, No. 184 and No. 189) significant ( $\mathrm{P}<0.01$ ) out yielded the better parent in lint yield/plant
and seed cotton yield/plant, four of them (family No. 95, No. 128, No. 147 and No. 184) gave significant earliness index from the better parent Giza 91 (Table 6). The average direct observed gain was significant ( $\mathrm{P}<0.05$ ) and accounted for 6.68 and $7.87 \%$ from the bulk sample and the better parent; respectively. Two selected families could be considering promising families; No. 128 and no. 184. These two families show significant ( $\mathrm{P}<0.01$ ) direct gain in lint yield/plant and significant correlated gains in most of the studied traits, especially earliness index (Table 7).
3.3- Means and observed gain in pop. II:
Mean lint yield/plant ranged from 11.89 to 22.63 with an average of 16.07 g . Four families (No. 16, No. 73, No. 151 and No. 160 ) out yielded the bulk sample with a range from 11.29 to $36.09 \%$ (Table 8). The four families showed significant correlated response in seed cotton yield/plant, number of bolls/plant and days to first flower, three of them showed significant correlated response in earliness index. Five families (No. 16, No. 73, No. 151, No. 160 and No. 182) showed significant ( $\mathrm{P}<0.01$ ) direct response form the better parent ranged from 9.49 to $54.47 \%$ (Table 8). The over all mean of the ten selected families showed significant ( $\mathrm{P}<0.01$ ) direct response of $9.69 \%$ from the better parent (Table 7). Selection for lint yield/plant in pop. II, resulted in two superior promising families; No. 151 and No. 160, Fam-
ily No. 160 showed significant ( $\mathrm{P}<0.01$ ) direct gain in lint yield/plant of $14.77 \%$ from the bulk sample and $19.39 \%$ from the better parent accompanied with significant correlated gain in earliness index of 7.37 and $2.41 \%$ from the bulk sample and the better parent; respectively. These results are in agreement with those reported by Mahdy et al. (2001a), El-Okkiah et al. (2008), Mahdy et al. (2009b), Hassaballa et al. (2012) and Mahdy et al. (2012).
